Abstract

We extend a variant of a predictor-corrector primal-dual method for Linear Programming to Semidefinite Programming. Two versions are proposed. One of the versions uses the HKM direction and the other the NT direction. We present the algorithms associated with these versions and the computational experience using the SDPLIB 1.2 collection of Semidefinite Programming test problems. We show that, in general, the algorithm using the HKM direction is the best and is also better than the one relative to the classical method.

Keywords: Semidefinite Programming, predictor-corrector interior point variant, HKM direction, NT direction.

1 Introduction

Semidefinite Programming, SDP, is a recent, but important, field of Mathematical Programming and, although its roots are older [3, 12], most of its remarkable advances were made in the 90’s [1, 14]. With this work, we intend to obtain a predictor-corrector primal-dual interior
point algorithm with better performance and more precise than the other algorithms of the same type already known.

Many interior-point methods for SDP are extensions of the methods that already exist for Linear Programming, LP [1, 14]. In [2] a variant of Mehrotra’s predictor-corrector method for LP was presented and it was shown to be more efficient than the original for the class of problems studied in that work. We propose a new variant for SDP that is an extension of that one for LP.

We present two versions of the new variant. One of them uses a direction, that was independently proposed by Helmberg, Rendl, Vanderbei and Wolkowicz in [8] and Kojima, Shindoh and Hara [11] and later rediscovered by Monteiro [13], which is usually referred as HKM direction. The other version uses the NT direction introduced by Nesterov and Todd in [15]. We also compare the results of these versions and the ones obtained with the classical method.

This paper is organized as follows. In Section 2, we present some useful notions and results about Semidefinite Programming and the solution of the the Lyapunov equation

\[ AX + XA^T = H, \]

with \( A \in S_n^{++} \) and \( H \in M_n \). In Section 3, the primal-dual and the predictor-corrector algorithms, bases of the new variant, are described. In Section 4, the version of the variant with the HKM direction is presented. In Section 5, the NT direction for the new variant is computed and the corresponding version of the variant is presented. In Section 6, the computational experience is described. A brief description of the used tools is given and the obtained results with the new versions and the classical method are compared.

2 Preliminaries

The set of real \( m \times n \) matrices, \( M_{m,n} \), is a real vector space isomorphic to \( \mathbb{R}^{mn} \). In this vector space we define the inner product between \( A, B \in M_{m,n} \) by

\[ \langle A, B \rangle = \text{Tr} (B^T A) = \sum_{i=1}^{m} \sum_{j=1}^{n} a_{ij} b_{ij}, \]

where \( \text{Tr} (\cdot) \) represents the trace, which is the sum of the main diagonal entries of a matrix. The associated norm, \( \langle A, A \rangle^{1/2} \), is called Frobenius norm and is represented by \( ||A||_F \). The particular case of the square matrices of order \( n \) will be represented by \( M_n \). The set of real symmetric matrices of order \( n \), \( S_n = \{ A \in M_n : A^T = A \} \), is a subspace of \( M_n \) isomorphic to \( \mathbb{R}^{n(n+1)/2} \). For \( A, B \in S_n \) \( \langle A, B \rangle = \text{Tr} (AB) \). The set of positive semidefinite matrices, \( S_n^+ \), is a full dimensional, non polyhedral convex cone in \( S_n \) and induces a partial order on the set of symmetric matrices. We write \( A \succeq B \) if \( A - B \in S_n^+ \). The interior of the cone \( S_n^+ \) is the set of positive definite matrices and is denoted by \( S_n^{++} \). Similarly, \( A \succ B \) means that \( A - B \in S_n^{++} \).

Consider the matrices \( A_i \in S_n, i = 1, \ldots, m \) and the linear operator \( A : S_n \rightarrow \mathbb{R}^m \) defined...
by
\[ A(X) = \begin{bmatrix} \langle A_1, X \rangle \\ \vdots \\ \langle A_m, X \rangle \end{bmatrix}. \]

The adjoint operator of \( A \), the operator \( A^T : \mathbb{R}^m \rightarrow \mathcal{S}_n \) defined by \( \langle A(X), y \rangle = \langle X, A^T(y) \rangle \), for all \( X \in \mathcal{S}_n \) and \( y \in \mathbb{R}^m \), is \( A^T(y) = \sum_{i=1}^{m} y_i A_i \).

The standard primal-dual pair of Semidefinite Programming problems is

\[
\begin{align*}
\text{(P)} \quad & \min_X \langle C, X \rangle \\
\text{s.t.} \quad & A(X) = b \\
& X \succeq 0
\end{align*}
\]

\[
\begin{align*}
\text{(D)} \quad & \max_{y,Z} b^T y \\
\text{s.t.} \quad & A^T(y) + Z = C \\
& Z \succeq 0,
\end{align*}
\]

where \( C \in \mathcal{S}_n \) and \( b \in \mathbb{R}^m \).

The primal problem is (P) while (D) is the Lagrangian dual of (P). Any \( X ((y, Z)) \) that satisfy the constraints of (P) ((D)) is called a feasible solution of (P) ((D)). If \( X ((y, Z)) \) is a feasible solution of (P) ((D)) and \( X > 0 \) \((Z > 0)\) then \( X ((y, Z)) \) is called a strictly feasible solution of (P) ((D)).

Any primal-dual pair of feasible solutions verifies the relation \( \langle C, X \rangle - b^T y = \langle X, Z \rangle \succeq 0 \), called weak duality property. If \( \langle X, Z \rangle = 0 \), then the primal-dual pair \((X, Z)\) is optimal but the reciprocal is not true, that is, the strong duality property is not always true. A sufficient condition for the optimal values of (P) and (D) be the same is the existence of strictly feasible solutions for both the primal and the dual problems.

We end this section with a result that gives the solution of the Lyapunov equation

\[ AX + X A^T = H, \quad (2) \]

with \( A \in \mathcal{S}^{++} \) and \( H \in \mathcal{M}_n \) known [10].

Let us first introduce the definition of Hadamard product [9], necessary to the next theorem.

**Definition 2.1.** The Hadamard product of \( A = [a_{ij}], B = [b_{ij}] \in \mathcal{M}_{m,n} \) is \( A \odot B = [a_{ij}b_{ij}] \).

**Theorem 2.1.** Let \( A \in \mathcal{S}_n^{++} \) be a matrix satisfying \( A = SAS^T \), \( S, \Lambda \in \mathcal{M}_n \), \( S \) orthogonal and \( \Lambda = \text{Diag}(\lambda_1(A), \ldots, \lambda_n(A)) \), where \( \lambda_i(A), \ i = 1, \ldots, n \) are the eigenvalues of \( A \). Consider that \( H \in \mathcal{M}_n \), then the solution of (2) is

\[ X = S[L \odot (S^T HS)]S^T, \]

with \( L = [l_{ij}] \), where \( l_{ij} = (\lambda_i(A) + \lambda_j(A))^{-1} \).

### 3 A primal-dual method and a classical predictor-corrector variant

The SDP algorithms presented in this paper correspond to different versions of a new predictor-corrector variant of the primal-dual method developed by Christopher Helmberg, Franz Rendl,
Robert J. Vanderbei and Henry Wolkowicz [8]. In this section we will briefly describe the infeasible versions of this primal-dual method and of the classical predictor-corrector variant.

Although it is not needed a feasible solution, the method requires the existence of an initial primal-dual pair \((X^0, Z^0)\) satisfying \(X^0, Z^0 \in S_n^{++}\).

The primal barrier problem is

\[
\text{PB}(\mu) : \min_X \langle C, X \rangle - \mu \ln(\det(X))
\]

\[\text{s.a} \quad A(X) = b,
\]

where \(\mu > 0\) is the barrier parameter.

For each \(\mu\), the corresponding Lagrangean is

\[
L_\mu(X, y) = \langle C, X \rangle - \mu \ln(\det(X)) + \langle y, b - A(X) \rangle.
\]

The first order optimality conditions for \(\text{PB}(\mu)\), necessary and sufficient in this case, are

\[
\nabla_X L_\mu = C - \mu X^{-1} - A^T(y) = 0
\]

\[
\nabla_y L_\mu = b - A(X) = 0.
\]

Taking \(Z = \mu X^{-1}\) we can rewrite these conditions in the following form

\[
\text{CPS}(\mu) \begin{cases}
A(X) = b \\
A^T(y) + Z = C \\
XZ = \mu I \\
X > 0 \\
Z > 0.
\end{cases}
\]

(3)

The set of solutions of \(\text{CPS}(\mu)\) for \(\mu > 0\),

\[
C = \{(X_\mu, y_\mu, Z_\mu) : \mu > 0\}.
\]

is called central path. Note that, for a point \((X, y, Z)\) in the central path we obtain \(\mu = \langle X, Z \rangle / n\).

Given \((X, y, Z) \in C\) we want to find a search direction \((\Delta X, \Delta y, \Delta Z)\) so that \((X + \Delta X, y + \Delta y, Z + \Delta Z)\) is still in the central path. Let

\[
F_\mu(p) = \begin{bmatrix}
A(X) - b \\
A^T(y) + Z - C \\
XZ - \mu I
\end{bmatrix},
\]

(4)

with \(p = (X, y, Z)\). Using Newton’s method we can obtain a search direction \(\Delta p = (\Delta X, \Delta y, \Delta Z)\) by solving

\[
F_\mu(p) + \nabla F_\mu(p) \Delta p^T = 0.
\]

This system can be written as...
\[
\text{NFS}(\mu) \begin{cases} \mathcal{A}(\Delta X) = F_p \\ \mathcal{A}^T(\Delta y) + \Delta Z = F_d \\ \Delta XZ + X\Delta Z = \mu I - XZ, \end{cases} \tag{5}
\]

where \( F_p = b - \mathcal{A}(X) \) and \( F_d = C - Z - \mathcal{A}^T(y) \).

Rewriting NFS(\mu) we obtain

\[
\begin{cases} \mathcal{A}(X\mathcal{A}^T(\Delta y)Z^{-1}) = -\mu \mathcal{A}(Z^{-1}) + b + \mathcal{A}(XF_dZ^{-1}) \\ \Delta Z = F_d - \mathcal{A}^T(\Delta y) \\ \Delta X = \mu Z^{-1} - X - XF_dZ^{-1} + X\mathcal{A}^T(\Delta y)Z^{-1}. \end{cases} \tag{6}
\]

From the first equation we get \( \Delta y \) and, replacing it in the remaining equations, we get \( \Delta X \) and \( \Delta Z \). The obtained \( \Delta Z \) is symmetric, consequence of the second equation, but, as \( X \) and \( Z \) do not commute, this is not the case for \( \Delta X \). As the first and the third components of the next iterate must belong to \( \mathcal{S}_n^{++} \) we have to obtain a symmetric \( \Delta X \). There are several ways of doing this, one of them is just using the symmetric part of \( \Delta X \), that is, supposing that \( (\overline{\Delta X}, \Delta y, \Delta Z) \) is the solution of (6) then, our search direction will be \( (\Delta X, \Delta y, \Delta Z) \) with \( \Delta X = (\overline{\Delta X} + (\overline{\Delta X})^T)/2 \). This search direction is known as \textit{HRVW/KSH/M direction}.

In each iteration, two step lengths are computed, one associated with the primal direction, \( \alpha_p \), and the other with the dual, \( \alpha_d \). Both values are obtained using the backtracking method. After computing \( \alpha_p \) and \( \alpha_d \) the algorithm moves from the current iterate \((X, y, Z)\) to the next iterate

\[(X + \alpha_p \Delta X, y + \alpha_d \Delta y, Z + \alpha_d \Delta Z).\]

Brian Borchers [4] developed an infeasible predictor-corrector variant of the primal-dual method presented in [8]. We will call it \textit{classical predictor-corrector}, PCC. In this variant, to obtain the search direction we assume that is possible to take a step of length one in the direction \((\Delta X, \Delta y, \Delta Z)\) and replace in the first three equations of CPS(\mu), in (3), the current iterate \((X, y, Z)\) by the new iterate \((X + \Delta X, y + \Delta y, Z + \Delta Z)\). The result is the system

\[
\begin{cases} \mathcal{A}(\Delta X) = F_p \\ \mathcal{A}^T(\Delta y) + \Delta Z = F_d \\ X\Delta Z + X\Delta Z = \mu I - XZ - \Delta X\Delta Z. \end{cases} \tag{7}
\]

To obtain the predictor direction, in (7) we take \( \mu = 0 \) and neglect the non-linear term \( \Delta X\Delta Z \). Solving this system we get the triple \((\overline{\Delta X^o}, \Delta y^o, \Delta Z^o)\) satisfying

\[
\begin{cases} \mathcal{A}(X\mathcal{A}^T(\Delta y^o)Z^{-1}) = b + \mathcal{A}(XF_dZ^{-1}) \\ \Delta Z^o = F_d - \mathcal{A}^T(\Delta y^o) \\ \overline{\Delta X^o} = -X - XF_dZ^{-1} + X\mathcal{A}^T(\Delta y^o)Z^{-1}, \end{cases}
\]

with \( F_d = C - Z - \mathcal{A}^T(y) \). As in the primal-dual case, the predictor direction \((\Delta X^o, \Delta y^o, \Delta Z^o)\) is obtained symmetrizing \( \overline{\Delta X^o} \).

The corrector direction is also obtained from (7). We use \((\Delta X^o, \Delta y^o, \Delta Z^o)\) to compute \( \mu \) and to approximate the non-linear term \( \Delta X\Delta Z \) by \( \Delta X^o\Delta Z^o \). The final direction is the
sum of the predictor and the corrector directions, that is, we take \((\Delta X, \Delta y, \Delta Z) = (\hat{\Delta}X, \hat{\Delta}y, \hat{\Delta}Z)\). Now, considering the conditions satisfied by the predictor direction we obtain the following system

\[
\begin{align*}
A(\hat{\Delta}X) &= 0 \\
A^T(\hat{\Delta}y) + \Delta Z &= 0 \\
\hat{\Delta}XZ + X\Delta Z &= \mu I - \Delta X^o \Delta Z^o.
\end{align*}
\] (8)

From (8) we get the triple \((\hat{\Delta}X, \hat{\Delta}y, \Delta Z)\) satisfying

\[
\begin{align*}
A(XA^T(\hat{\Delta}y)Z^{-1}) &= -A(\mu Z^{-1} - \Delta X^o \Delta Z^o Z^{-1}) \\
\Delta Z &= -\hat{\Delta}Z \\
\hat{\Delta}X &= \mu Z^{-1} - \Delta X^o \Delta Z^o Z^{-1} + XA^T(\hat{\Delta}y)Z^{-1}.
\end{align*}
\]

We obtain the corrector direction \((\Delta X^c, \Delta y^c, \Delta Z^c)\) after symmetrizing \(\hat{\Delta}X^c\). The final direction is

\[ (\Delta X, \Delta y, \Delta Z) = (\Delta X^o + \Delta X^c, \Delta y^o + \Delta y^c, \Delta Z^o + \Delta Z^c). \]

In the classical predictor-corrector algorithm, like in the primal-dual, different choices for the primal and dual step lengths are made, using the backtracking method. In each iteration,

\[
\begin{align*}
\alpha_k^p &= 0.99 \sup_{\alpha \in [0, 1]} \{ \alpha : X^k + \alpha \Delta X^k \succ 0 \} \\
\alpha_k^d &= 0.99 \sup_{\alpha \in [0, 1]} \{ \alpha : Z^k + \alpha \Delta Z^k \succ 0 \}.
\end{align*}
\] (9)

To obtain the supreme, we begin with \(\alpha = 1\) and \(\alpha\) is actualized to be 90% of the previous \(\alpha\), this is, \(\alpha_{\text{new}} = 0.9 \alpha_{\text{old}}\).

The computation of the duality measure, \(\mu\), is not only based on the quantities \(\langle X, Z \rangle/n\) and \(\langle X, Z \rangle/2n\) but it also uses two line searches associated with the predictor direction.

The initial solution used is

\[
\begin{align*}
X^0 &= 100\alpha I, \\
y &= 0, \\
Z^0 &= 100\beta I,
\end{align*}
\] (10)

with

\[
\alpha = n \max_{1 \leq i \leq m} \frac{1 + |b_i|}{1 + \|A_i\|_F},
\]

\[
\beta = 1 + \max_{1 \leq i \leq m} \left( \frac{\|A_i\|_F, \|C\|_F} {\sqrt{n}} \right).
\] (11)

Finally, the termination criteria is

\[
\begin{align*}
\frac{\|b - A(X^k)\|_2}{1 + \|b\|_2} \leq 1.0 \times 10^{-06}; \\
\frac{\|C - A^T(y^k) - Z^k\|_F}{1 + \|C\|_F} \leq 1.0 \times 10^{-06} \\
\frac{|\langle C, X^k \rangle - b^T y^k|}{1 + |b^T y^k|} \leq 1.0 \times 10^{-07}; \\
X^k \succ 0; \quad Z^k \succ 0.
\end{align*}
\] (12)
4 A new predictor-corrector variant

From the previous section, we know that the classical predictor-corrector algorithm performs four line searches by iteration, two of them after obtaining the predictor direction to estimate the duality measure and the other two after computing the final direction. The algorithm we extend from LP [2] just makes two line searches per iteration and so it has the advantage of decreasing the running time of each iteration.

The major differences between this new variant and the classical predictor-corrector for LP are:

- the predictor direction is computed as in the primal-dual method;
- it uses the same $\mu$ for both the predictor and the corrector directions;
- to obtain $\mu$ no line search is needed.

We first tried to extend this variant to SDP literally. In particular, we used $\mu = \langle X, Z \rangle / 2n$, indicated in [8] as a good heuristic for the primal-dual algorithm, in the predictor and corrector steps. We verified that this option did not work in this context. We also tried some other heuristics mentioned in [2] such as

$$\mu = \frac{\langle X, Z \rangle}{2n^2}, \quad \text{with} \quad \theta(n) = \begin{cases} n^2 & \text{if } n \leq 5000 \\ n\sqrt{n} & \text{if } n > 5000, \end{cases}$$

always using the same $\mu$ in both steps.

After some computational experience, we verified that we could get substantial improvements if we consider different values of $\mu$ in the predictor and corrector steps. From that computational experience we concluded that the best heuristics for $\mu$ are:

$$\mu = \mu_p = \frac{\langle X, Z \rangle}{2n^2}, \quad \text{in the predictor step}$$

$$\mu = \mu_c = \frac{\langle X, Z \rangle}{2n^{3/4}}, \quad \text{in the corrector step.} \quad (13)$$

These expressions for the duality measure, although basically empirical, have some theoretical foundation. Let us assume this is a feasible method, that is, $F_p = 0$ and $F_d = 0$ in NFS($\mu$), (5). Then, at $k$-th iteration

$$\langle C, X^k \rangle - \langle b, y^k \rangle = \langle A^T(y^k) + Z^k, X^k \rangle - \langle A(X^k), y^k \rangle$$

$$= \langle A^T(y^k) + Z^k, X^k \rangle - \langle A^T(y^k), X^k \rangle$$

$$= \langle Z^k, X^k \rangle.$$ 

Suppose now that, instead of considering $\alpha_p^k$ and $\alpha_d^k$, we would consider $\alpha^k = \min\{\alpha_p^k, \alpha_d^k\}$. Then, we would get

$$\langle C, X^{k+1} \rangle - \langle b, y^{k+1} \rangle = \langle Z^{k+1}, X^{k+1} \rangle = \langle Z^k + \alpha^k \Delta Z^k, X^k + \alpha^k \Delta X^k \rangle$$

$$= \langle C, X^k \rangle - \langle b, y^k \rangle + \alpha^k (\langle Z^k, \Delta X^k \rangle + \langle \Delta Z^k, X^k \rangle) + (\alpha^k)^2 \langle \Delta Z^k, \Delta X^k \rangle.$$
On the other side, from the third equation of NFS(\(\mu\)), (5), we have \(\text{Tr}(\Delta X^k Z^k + X^k \Delta Z^k) = \text{Tr}(\mu^k I - X^k Z^k)\) that is equivalent to
\[
\langle Z^k, \Delta X^k \rangle + \langle \Delta Z^k, X^k \rangle = n \mu^k - \langle Z^k, X^k \rangle.
\]
Furthermore, using the definition of adjoint operator and the assumption of the method being feasible, we obtain
\[
\langle \Delta Z^k, \Delta X^k \rangle = \langle -A^T(\Delta y^k), \Delta X^k \rangle = -\langle A(\Delta X^k), \Delta y^k \rangle = \langle 0, \Delta y^k \rangle = 0.
\]
Then, \(\langle C, X^{k+1} - b, y^{k+1} \rangle = \langle C, X^k - b, y^k \rangle + \alpha^k \left( n \mu^k - \langle Z^k, X^k \rangle \right)\). This allows us to conclude that
\[
\langle C, X^{k+1} - b, y^{k+1} \rangle < \langle C, X^k \rangle - \langle b, y^k \rangle
\]
if
\[
\mu^k < \frac{\langle Z^k, X^k \rangle}{n}.
\]

Both options for \(\mu^k\) in (13) satisfy (14). But, as the method is not feasible and we do not use \(\alpha^k = \min\{\alpha^k_p, \alpha^k_c\}\), we cannot guarantee a decrease of \(\langle C, X \rangle - \langle b, y \rangle\). However, in practice, we verified that these options are much better than any other already proposed.

To implement this new variant we first used the HKM direction and the backtracking method to compute the step length, as in the classical predictor-corrector. For the backtracking method the proceeding is similar to the one described in (9), but the new \(\alpha\) is chosen as 85% of the previous one and not 90% as it happened before. This version of the new variant can be formalized in the following algorithm:

**Algorithm 1 - BHMK**

**Require:** \((X^0, y^0, Z^0)\) satisfying (10) and (11);
Take \(k = 0;\)

while the termination criteria (12) is not satisfied do

(a) Take \(\mu^k_p = \sigma^k \langle X^k, Z^k \rangle \), with \(\sigma^k \in [0, 1];\)
(b) Solve system (6) for \((\Delta X^{\sigma^k}, \Delta y^{\sigma^k}, \Delta Z^{\sigma^k})\), considering \(\mu = \mu^k_p;\)
Symmetrize \(\Delta X^{\sigma^k}\) to get \((\Delta X^{\sigma^k}, \Delta y^{\sigma^k}, \Delta Z^{\sigma^k});\)
(c) Take \(\mu^k_c = \sigma^k \langle X^k, Z^k \rangle \), with \(\sigma^k \in [0, 1];\)
(d) Solve system (8) for \((\Delta X^{\sigma^k}, \Delta y^{\sigma^k}, \Delta Z^{\sigma^k})\), considering \(\mu = \mu^k_c;\)
Symmetrize \(\Delta X^{\sigma^k}\) to get \((\Delta X^{\sigma^k}, \Delta y^{\sigma^k}, \Delta Z^{\sigma^k});\)
(e) Take \((\Delta X^k, \Delta y^k, \Delta Z^k) = (\Delta X^{\sigma^k}, \Delta y^{\sigma^k}, \Delta Z^{\sigma^k}) + (\Delta X^{\sigma^k}, \Delta y^{\sigma^k}, \Delta Z^{\sigma^k});\)
(f) Compute \(\alpha^k_c\) and \(\alpha^k_d\) using (9) with \(\alpha_{new} = 0.85\alpha_{old};\)
(g) Take \(X^{k+1} = X^k + \alpha^k_p \Delta X^k\) and \((y^{k+1}, Z^{k+1}) = (y^k, Z^k) + \alpha^k_d(\Delta y^k, \Delta Z^k);\)
(h) Take \(k = k + 1;\)
end while

**5 The new predictor-corrector variant with NT direction**

Another direction that is often used in practice and also theoretically studied is due to Nesterov and Todd and is called **NT direction** [15, 16, 17]. Thus, we decided to implement this direction
in our predictor-corrector variant.

As this direction is not directly obtained, as it happens with HKM, we will present its computation. Once more, we will assume that it is possible to take a step of length one in the direction \((\Delta X, \Delta y, \Delta Z)\). This way we get the system

\[
\begin{align*}
A(\Delta X) &= F_p \\
A(\Delta y) + \Delta Z &= F_d \\
(X + \Delta X)(Z + \Delta Z) &= \mu I,
\end{align*}
\]  

with \(F_p = b - A(X)\) and \(F_d = C - Z - A^T(y)\).

The NT direction is obtained using a scaling matrix to reformulate the third equation of (15), so that the solution of the new system is symmetric. Let us consider the Cholesky factorizations of \(X\) and \(Z\), \(X = LL^T\) and \(Z = RR^T\), the singular value decomposition of \(R^T L\), \(UDV^T = R^T L\), and the scaling matrix \(W = X^{1/2}(X^{1/2} Z X^{1/2})^{-1/2} X^{1/2}\). It can be shown that \(W\) satisfies the condition \(W^{-1} X = Z W\) and that it can be written as \(W = G G^T\), with \(G = L V D^{-1/2}\) [17]. Then, \(G^{-1} X G^{-T} = G^T Z G\).

Consider now \(D = G^{-1} X G^{-T} = G^T Z G\), \(D_X = G^{-1} X G^{-T}\) and \(D_Z = G^T D Z G\). Thus, the third equation of (15) is equivalent to \((D + D_X)(D + D_Z) = \mu I\). Weakening this equation, by replacing the left member by its symmetric part, we get

\[
\frac{1}{2} [(D_X + D_Z)D + D(D_X + D_Z)] = \mu I - D^2 - \frac{1}{2} (D_X D Z + D_Z D_X). \tag{16}
\]

To obtain the predictor direction we take \(\mu = \mu_p\) and neglect the non-linear terms in (16). This way we get a Lyapunov equation in \(D_X + D_Z\) which has the symmetric solution \(\mu_p D^{-1} - D\). Multiplying both members of

\[
D_X + D_Z = \mu_p D^{-1} - D
\]

by \(G\) on the left and \(G^T\) on the right we get

\[
\Delta X^o = \mu_p Z^{-1} - X - W \Delta Z^o W.
\]

This equation, jointly with (15), allow us to obtain

\[
\begin{align*}
A(\Delta X^o) &= F_p \\
A^T(\Delta y^o) + \Delta Z^o &= F_d \\
\Delta X^o &= \mu_p Z^{-1} - X - W \Delta Z^o W.
\end{align*}
\]  

Solving (17) we get the triple \((\Delta X^o, \Delta y^o, \Delta Z^o)\) satisfying

\[
\begin{align*}
A(W A^T(\Delta y^o) W) &= A(W F_d W + X - \mu_p Z^{-1}) + F_p \\
\Delta Z^o &= F_d - A^T(\Delta y^o) \\
\Delta X^o &= \mu_p Z^{-1} - X - W F_d W + W A^T(\Delta y^o) W.
\end{align*}
\]  

The corrector direction is obtained taking in (16) \(D_X = D_X^c + D_X^s\), \(D_Z = D_Z^c + D_Z^s\) and \(\mu = \mu_p + \mu_c\). The non-linear terms \(D_X D_Z\) and \(D_Z D_X\) are also approximated by \(D_X^c D_Z^c\) and
D^2_c D^h_c$, respectively. Then, considering the conditions satisfied by the predictor direction, we can write

$$(D^h_c + D^c_Z)D + D(D^h_c + D^c_Z) = H_c,$$

with $H_c = 2\mu_c I - (D^c_X D^c_Z + D^c_Z D^c_X)$. By Theorem 2.1, the solution of this Lyapunov equation is $L \circ H_c$, with $L = [l_{ij}]$ where $l_{ij} = (d_i + d_j)^{-1}$ and $d_i$ and $d_j$ represent the $i$-th and the $j$-th entries of the diagonal matrix $D$, respectively. Multiplying both members of

$$D^h_c + D^c_Z = L \circ H_c$$

by $G$ on the left and by $G^T$ on the right we get

$$\Delta X^c = G(L \circ H_c)G^T - W \Delta Z^c W.$$  

(19)

Now, consider $D^c_X = G^{-1}\Delta X^o G^{-T}$, $D^c_Z = G^{-1}\Delta X^c G^{-T}$, $D^c_X = G^T \Delta Z^c G$ and $D^c_Z = G^T \Delta Z^o G$. Then, it is possible to show that the equalities $D_X = D^c_X + D^h_c$ and $D_Z = D^c_Z + D^h_c$ are equivalent to $\Delta X = \Delta X^o + \Delta X^c$ and $\Delta Z = \Delta Z^o + \Delta Z^c$, respectively. Furthermore, $D^c_X D^c_Z + D^c_Z D^c_X = G^{-1}\Delta X^o \Delta Z^o G + (G^{-1}\Delta X^c \Delta Z^c G)^T$. Thus, taking $(\Delta X, \Delta y, \Delta Z) = (\Delta X^o + \Delta X^c, \Delta y^o + \Delta y^c, \Delta Z^o + \Delta Z^c)$ and considering (19) and the conditions satisfied by the predictor direction we get the system

$$\begin{cases} 
A(\Delta X^c) = 0 \\
\Delta Z^c + A^T(\Delta y^c) = 0 \\
\Delta X^c = G(L \circ H_c)G^T - W \Delta Z^c W,
\end{cases}$$

(20)

with $H_c = 2\mu_c I - [(G^{-1}\Delta X^o \Delta Z^o G) + (G^{-1}\Delta X^c \Delta Z^c G)^T]$. The solution of (20) is the corrector direction $(\Delta X^c, \Delta y^c, \Delta Z^c)$ that satisfies

$$\begin{cases} 
A(W A^T(\Delta y^c) W) = -A(G(L \circ H_c)G^T) \\
\Delta Z^c = -A^T(\Delta y^c) \\
\Delta X^c = G(L \circ H_c)G^T + W A^T(\Delta y^c) W.
\end{cases}$$

The final direction, $(\Delta X, \Delta y, \Delta Z)$, is obtained adding the predictor and the corrector directions.

From the computational experience with this version we verified that we got better results when we used a different heuristic for the duality measure in the predictor direction,

$$\mu_p = \frac{\langle X, Z \rangle}{2.5n^2}.$$ 

The algorithm corresponding to the version of our predictor-corrector variant that uses NT direction will be called $BNT$ algorithm and differs from the BHKM algorithm in the following points:
(a) Take $\mu_k^p = \sigma_k^k \langle X^k, Z^k \rangle / 2.3n^2$, with $\sigma_k^k \in [0, 1]$;

(b) Solve system (17) for $(\Delta X^k, \Delta y^k, \Delta Z^k)$, considering $\mu_p = \mu_p^k$;

(d) Solve system (20) for $(\Delta X^c, \Delta y^c, \Delta Z^c)$, considering $\mu_c = \mu_c^k$;

6 Computational experience

Now, we will describe the computational experience that we have done to compare the two versions of our predictor-corrector variant and the classical predictor-corrector method, described in the previous sections.

6.1 Brief description of the used tools

The computational tests were performed in a Pentium III, 1100 Mhz, 245232 KB of RAM, with the 7.3 version of the Red Hat Linux operating system and the 2.96 version of the gcc compiler. To implement the new predictor-corrector variant we used the 3.2 version of the source code of the package CSDP by Brian Borchers [4, 6, 7]. The code was modified to achieve two main purposes: it was adapted to be possible to implement the different versions of the predictor-corrector variant and it was optimized to become faster and more robust.

To compare the performance of the algorithms we used the SDPLIB 1.2 collection of SDP test problems [5]. It has 92 problems in a wide range of sizes and drawn from many different applications, including truss topology design, control systems engineering and combinatorial optimization. It also includes primal and dual infeasible instances.

6.2 Results

We will present the results corresponding to both versions of the predictor-corrector variant described earlier and compare those results with the ones obtained with the classical predictor-corrector algorithm (PCC algorithm). We will use tables with information about the number of iterations, It, the total CPU time (in seconds), T, and the relative duality gap, RDgap. We will also include information about the relative admissibility, that specifies if the algorithm stops with a solution that is far from satisfying any of the admissibility criteria or not. All the solutions obtained satisfy the relative dual admissibility termination criteria but the same does not happen with the primal one. Thus, in RDgap column will appear * if the relative primal admissibility belongs to $[1.0 \times 10^{-06}, 1.0 \times 10^{-03}]$ and ** if it is non inferior to $1.0 \times 10^{-03}$. In all the experiences we used (12) as termination criteria and (10), satisfying (11), as initial solution.

Due to memory problems it was not possible to obtain any results for the problems maxG55 and maxG60, so they were not included in the tables. For the same reason, it was also not possible to obtain some results with the BNT algorithm. In this case, the fields of the table will contain $\text{m}$.

In the next section we will analyse the results presented.

Table 3: BNT algorithm
6.3 Analysis of the results

To help the analysis of the previous tables, for each class of problems, we will construct graphics with information about the time and the number of iterations. As the running times of the problems in $hinf$, $inf$ and $truss$ classes are very small, we do not present the corresponding graphics with the time information. Furthermore, when, for a certain class, the amplitude of the interval of time is too big we will present two graphics to facilitate the reading.

![Figure 1: Number of iterations for the arch class.](image1)

![Figure 2: Time, in seconds, for the arch class.](image2)

As we can observe in Figure 1, for the arch class the algorithms that performed less and more iterations were PCC and BNT, respectively. From Figure 2 we can conclude that BHKM was the fastest while BNT was the most time consuming.

![Figure 3: Number of iterations for the control class.](image3)

Consider now the control class. In Figure 3 is possible to observe that PCC was the algorithm with less iterations while the other two presented similar means for the number of iterations. For the time, Figures 4 and 5, all the algorithms presented identical means.
For the control class, the algorithm with less iterations was BHKM while the one with more was BNT, Figure 6. These positions were inverted for the time, Figure 7.

For the equalG class, the algorithm with less iterations was BNT while the one with more was BHKM, Figure 6. These positions were inverted for the time, Figure 7.

Relatively to the gpp class, we can observe in Figure 8 that the algorithms with less iterations were BHKM and BNT, being the first one the fastest and the second the slowest, Figures 9 and 10.
Consider now the $maxG$ class. Due to memory problems, it was not possible to obtain any results for $maxG32$ with BNT. But, in general, this algorithm was the worst one for the remaining problems. PCC was the algorithm that presented less iterations, Figure 11. PCC and BHKM spent similar amounts of time, Figure 12.

For the $mcp$ class, in Figure 13 is possible to see that PCC was the algorithm with less iterations while BHKM was the one with more. But, this last one was the fastest, being BNT the most expensive, Figures 14 and 15.

For the $gap$ class, the best and the worst algorithms were PCC and BHKM, respectively, Figures 16, 17 and 18.
Figure 13: Number of iterations for the \textit{mcp} class.

Figure 14: Time, in seconds, for the problems \textit{mcp100} to \textit{mcp250-4}.

Figure 15: Time, in seconds, for the problems \textit{mcp500}.
Consider, now, the $qpG$ class. Due to memory problems, it was not possible to obtain any results with BNT. Once more, BHKM was the algorithm with more iterations, Figure 19, but also the fastest, Figure 20.

From Figures 21 and 22 is possible to conclude that, for the $ss30$ problem, BHKM and BNT were the algorithms that presented less iterations being the first one the fastest and the second one the slowest.
As it happened before, due to memory problems, it was not possible to obtain any results for thetaG51 with BNT. For thetaG11 this algorithm was the most expensive. As we can see in Figures 23 and 24, the BHKM algorithm was the best one for the thetaG class.

From Figures 25, 26 and 27 we can conclude that PCC was the best algorithm for the theta class, while BHKM was the one with more iterations and BNT was the slowest.
It remains to analyse the results relating to \textit{truss}, \textit{hinf} and \textit{inf} classes. As these problems are of quick resolution we decided to study only the results about the number of iterations.

As we can see in Figure 28, for the \textit{hinf} class the algorithm that presented less iterations was BNT while the one with more was PCC.

For the \textit{truss} class, Figure 29, the algorithm with less iterations was PCC and the one with more was BHKM.

For the \textit{infd} problems, Figure 30, BHKM was the algorithm that took less iterations while BNT was the one with more. Finally, for the \textit{infp} problems, Figure 31, BNT was the best
algorithm while PCC was the worst.

![Graph showing number of iterations for the infd problems.](image2)

Figure 30: Number of iterations for the infd problems.

![Graph showing number of iterations for the infp problems.](image3)

Figure 31: Number of iterations for the infp problems.

To summarize we can say that:

- although BHKM was the algorithm that, in general, presented more iterations it was the fastest one;
- PCC was the algorithm that presented, for most of the cases, less iterations;
- BNT was the algorithm that spent more time.

For the classes of problems with results that satisfy all the termination criteria, the efficiency of the algorithms can be measured just in terms of the two previously analysed characteristics. For the other classes we considered that the efficiency should be measured in terms of how far the solution is from satisfying all those criteria. The control is one of these classes. For this class, PCC was the algorithm that performed better while BHKM and BNT presented similar behaviour. For the gpp class the only algorithm that stopped without satisfying all the termination criteria was PCC. The BHKM was the best algorithm for hinf and qap classes while PCC was the worst. As infd and infp are infeasible problems and problems with an infeasible dual, respectively, the values in RDgap do not mean, just by themselves, that the results were not satisfactory. All the algorithms solved the infd problems but only BNT solved the infp ones. Finally, for thetaG51 both PCC and BHKM presented similar results while, as already mentioned, due to memory problems it was not possible to obtain any results with BNT.
7 Final conclusions

From the obtained results we can conclude that, in general, the algorithm that uses the NT direction was the slowest and, due to memory problems, did not allow to obtain results for the problems with bigger dimensions. It was only better than the remaining algorithms for the infp problems. Although, for most of the problems, the BHKM algorithm needed more iterations than the others it was, in general, the fastest. Relatively to the classes of problems for which at least one of the algorithms ends without satisfying all the termination criteria, although PCC was the best for control class the BHKM was superior for gpp, hinf and gap classes, having both presented similar behaviour for the thetaG51 problem. Finally, we can conclude that the version of our predictor-corrector variant with HKM direction is better than the classical predictor-corrector for the generality of the problems.
